Abstract

The growing need for the adoption of tools capable of generating clean energy from renewable and sustainable sources has led to extensive generation and collection of energy production data, especially from photovoltaic panels installed worldwide. However, these data often have gaps and deficiencies due to various factors such as temporary failures, adverse weather conditions, or malfunctions of sensors and data collection instruments. Accurate imputation of these gaps is crucial to ensure the reliability of analyses and predictions based on this data. This thesis aims to address the problem of imputing time series data from photovoltaic panels using advanced deep learning techniques. In particular, a deep learning model based on Fully Connected Neural Networks (FCNN) and Recurrent Neural Networks (RNN) are proposed to capture the complex temporal relationships between the total energy produced (target feature) and various components of the system. The models were trained on a dataset consisting of real data from a photovoltaic system with a power capacity of approximately 1MW.

Chapter 1

Background

1.1 Problem Definition

The following thesis aims to address the problem of imputing time series data from photovoltaic systems. Specifically, it often happens that data acquisition instruments in a system temporarily fail, causing a period of time, more or less extended, where the curve of the total energy produced is missing. To try to fill this “gap” a simple formula is not sufficient, as various factors such as solar irradiance, ambient temperature, presence of clouds, rainfall, etc., need to be taken into account.

Formally, we can define the problem as follows:

Definition 1.1.1. Given:

- A set of time series data representing a photovoltaic system, $S = S_1, S_2, \dots, S_N$, where N represents the number of available time series;
- A target time series $t \in S$ that represent the Total Generated Energy;

Where each time series S_i is composed of ordered pairs (t_i, v_i) , where t_i is a timestamp representing the moment when the value v_i was recorded.

The objective of the imputation problem is to estimate the missing or damaged values in the time series t .

1.2 Photovoltaic Implant

Solar photovoltaic (PV) energy systems are made up of different components. Each component has a specific role. The type of component in the system depends on the type of system and the purpose. For example, a simple PV-direct system is

composed of a solar module or array (two or more modules wired together) and the load (energy-using device) it powers. A solar energy system produces direct current (DC). This is electricity which travels in one direction. The loads in a simple PV system also operate on direct current (DC). A stand-alone system with energy storage (a battery) will have more components than a PV- direct system.

1.2.1 Solar Module

The majority of solar modules available on the market and used for residential and commercial solar systems are silicon- crystalline. These modules consist of multiple strings of solar cells, wired in series (positive to negative), and are mounted in an aluminum frame. The size or area of the cell determines the amount of amperage. The larger the cell, the higher the amperage.

Figure 1.1: The solar cell is the basic component. Cells wired together and mounted in a frame compose a solar module. Several modules wired together form an array.

1.2.2 Solar Array

The solar array is made up of multiple PV modules wired together. Connecting the negative wire of one module to the positive wire of a second module is the beginning of a series string. Wiring modules in series results in the voltage of each of the two modules is added together. A series string represents the summed voltages of each individual module. The negative cable of one module is connected to the positive cable of the next module. In a large system, multiple strings are assembled and the non-connected ends are connected to homerun leads which are landed at the terminals of an enclosure located near the array. The goal is to wire modules in series to build voltage.

1.2.3 Junction Box

A PV system array with multiple strings of modules will have a positive lead and a negative lead on the end of each string. The positive leads will be connected to individual fuses and the negative leads will be connected to a negative busbar in an enclosure. This is called the source circuit. The junction box serves to “combine” multiple series strings into one parallel circuit. For example, an array with three strings of 10 modules wired in series would produce 300 volts (10 modules x 30 volts) per string and 4 amps per string. When the leads are landed in the combiner box, the circuit would produce 300 volts at 12 amps (3 strings x 4 amps/string). Once the circuits are combined, leaving the box it is referred to as the output circuit.

Figure 1.2: This figure represent an output circuit made of 3 string, each one hosts 10 solar modules.

1.2.4 Inverter

Energy from an array or a battery bank is direct current (DC). This will provide for DC loads such a lights, fans, pumps, motors, and some specialty equipment. However, if the energy is to be used to power loads that operate on alternating current (AC), as what is found in a residence, the current needs to be converted. The inverter changes DC energy to AC energy. Inverters are available in many different sizes for various-sized loads. A string inverter is used to convert DC power from a solar array to AC power and can be connected to an AC distribution power panel (service panel) in a residence or facility.

1.2.5 System Metering

Several tools are available to help the solar user to monitor their system. On stand-alone or off-grid PV systems, the battery meter is used to measure the energy coming in and going out of the battery bank. Charging and discharging of batteries, and proper functioning of the charging system is important to alert the user to incomplete charging, battery decline, or possible system shutdown. System monitoring with web-based tools and apps allow the solar user to see system activity using a cell phone or tablet from a location away from their system.

1.3 Multi Perceptron

The multilayer perceptron is the most known and most frequently used type of neural network. On most occasions, the signals are transmitted within the network in one direction: from input to output. There is no loop, the output of each neuron does not affect the neuron itself. This architecture is called feed- forward. Layers which are not directly connected to the environment are called hidden. There are also feed-back networks, which can transmit impulses in both directions, due to reaction connections in the network. These types of networks are very powerful and can be extremely complicated. Introduction of several layers was determined by the need to increase the complexity of decision regions. A perceptron with a single layer and one input generates decision regions under the form of semi planes. By adding another layer, each neuron acts as a standard perceptron for the outputs of the neurons in the anterior layer, thus the output of the network can estimate convex decision regions, resulting from the intersection of the semi planes generated by the neurons. The power of the multilayer perceptron comes precisely from non-linear activation functions. Almost any non-linear function can be used for this purpose, except for polynomial functions. Currently, the functions most commonly used today are the single-pole (or logistic) sigmoid.

Figure 1.3: Sigmoid function $\sigma(x) = \frac{1}{1+e^{-x}}$

Figure 1.4: Multi Layer Perceptron architecture.

1.4 Recurrent Neural Network

Recurrent Neural Networks (RNNs) are a type of neural network architecture which is mainly used to detect patterns in a sequence of data. Such data can be handwriting, genomes, text or numerical time series which are often produced in industry settings (e.g. stock markets or sensors). However, they are also applicable to images if these get respectively decomposed into a series of patches and treated as a sequence. On a higher level, RNNs find applications in Language Modelling

and Generating Text, Speech Recognition, Generating Image Descriptions or Video Tagging. What differentiates Recurrent Neural Networks from Feedforward Neural Networks also known as Multi-Layer Perceptrons (MLPs) is how information gets passed through the network. While Feedforward Networks pass information through the network without cycles, the RNN has cycles and transmits information back into itself. This enables them to extend the functionality of Feedforward Networks to also take into account previous inputs $X_{0:t-1}$ and not only the current input X_t . This difference is visualised on a high level in Figure 1.5. Note, that here the option of having multiple hidden layers is aggregated to one Hidden Layer block H . This block can obviously be extended to multiple hidden layers.

Feed Forward Neural Network

Recurrent Neural Network

Figure 1.5: Visualization of difference between MLPs and RNN.

1.4.1 Gated Recurrent Unit

Gated Recurrent Units (GRU) are an advanced variation of RNNs (Recurrent Neural Network). GRUs use update gate and reset gate for solving a standard RNNs vanishing gradient issue. These are essentially 2 vectors that decide the type of information to be passed towards the output. What makes these vectors special is that programmers can train them to store information, especially from long ago. They do all of this by utilizing its gated units which help solve vanishing/exploding gradient problems often found in traditional recurrent neural networks. These gates are helpful for controlling any information to be maintained or discarded for each step. It is also worth keeping in mind that gated recurrent units make use of reset and update gates.

- **Update Gates Function:** The main function of the update gate is to determine the ideal amount of earlier info that is important for the future.

One of the main reasons why this function is so important is that the model can copy every single past detail to eliminate fading gradient issue.

- **Reset Gate's Function:** A major reason why reset gate is vital because it determines how much information should be ignored. It would be fair to compare reset gate to LSTMs forget gate because it tends to classify unrelated data, followed by getting the model to ignore and proceed without it.

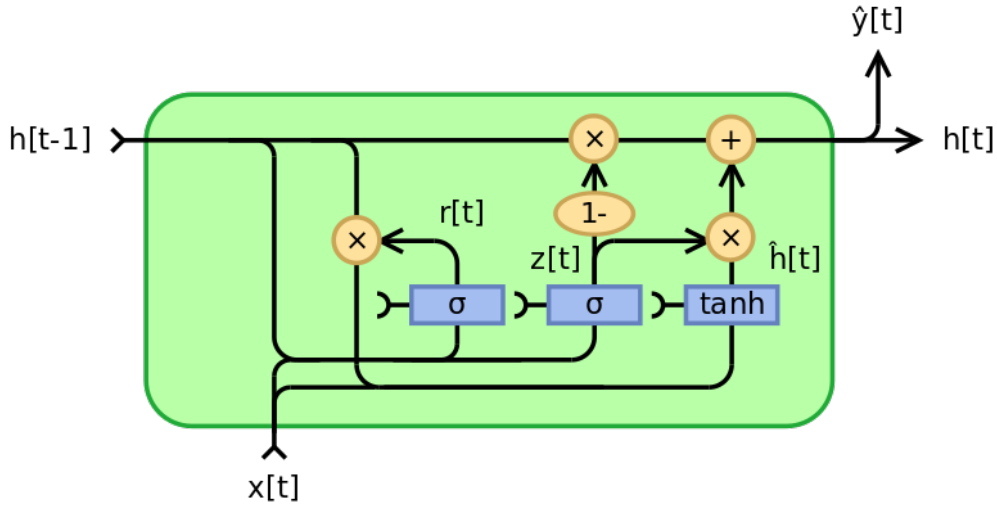

Figure 1.6: Gated Recurrent Unit (GRU) architecture.

1.5 Transformer

Recurrent neural networks, long short-term memory and gated recurrent neural networks in particular, have been firmly established as state of the art approaches in sequence modeling and transduction problems such as language modeling and machine translation. Recurrent models typically factor computation along the symbol positions of the input and output sequences. Aligning the positions to steps in computation time, they generate a sequence of hidden states h_t , as a function of the previous hidden state h_{t-1} and the input for position t . This inherently sequential nature precludes parallelization within training examples, which becomes critical at longer sequence lengths, as memory constraints limit batching across examples. Attention mechanisms have become an integral part of compelling sequence modeling and transduction models in various tasks, allowing modeling of dependencies without regard to their distance in the input or output sequences. The Transformer allows for significantly more parallelization.

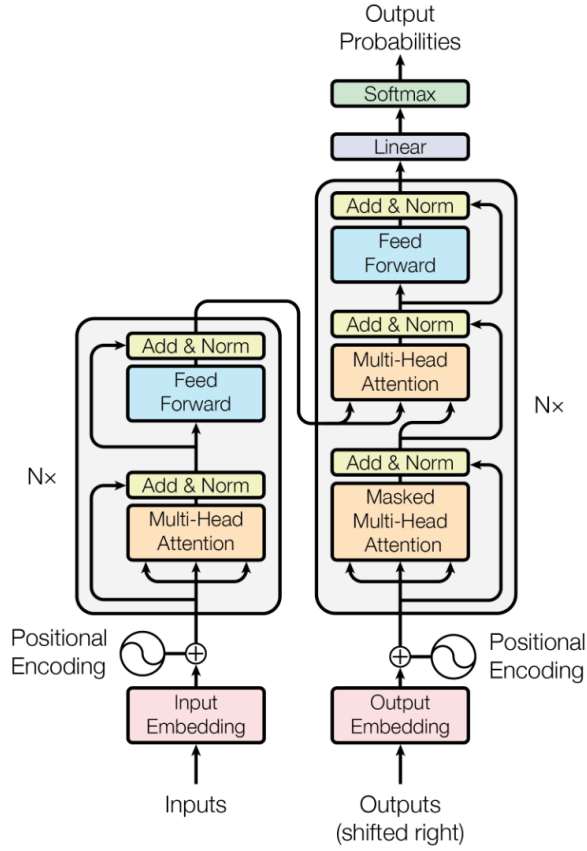

Figure 1.7: This figure shows the Transformers model architecture.

Most competitive neural sequence transduction models have an encoder-decoder structure. Here, the encoder maps an input sequence of symbol representations (x_1, \dots, x_n) to a sequence of continuous representations $z = (z_1, \dots, z_n)$. Given z , the decoder then generates an output sequence (y_1, \dots, y_m) of symbols one element at a time. At each step the model is auto-regressive, consuming the previously generated symbols as additional input when generating the next. The Transformer follows this overall architecture using stacked self-attention and point-wise, fully connected layers for both the encoder and decoder, shown in the left and right halves of Figure 1.7, respectively.

- *Encoder*: The encoder is composed of a stack of $N = 6$ identical layers. Each layer has two sub-layers. The first is a multi-head self-attention mechanism, and the second is a simple, position-wise fully connected feed-forward network. Residual connections are employed around each of the two sub-layers,

followed by layer normalization. That is, the output of each sub-layer is $\text{LayerNorm}(x + \text{Sublayer}(x))$, where $\text{Sublayer}(x)$ is the function implemented by the sub-layer itself. To facilitate these residual connections, all sub-layers in the model, as well as the embedding layers, produce outputs of dimension $d_{\text{model}} = 512$.

- *Decoder*: The decoder is also composed of a stack of $N = 6$ identical layers. In addition to the two sub-layers in each encoder layer, the decoder inserts a third sub-layer, which performs multi-head attention over the output of the encoder stack. Similar to the encoder, there are residual connections around each of the sub-layers, followed by layer normalization. The self-attention sub-layer is modified in the decoder stack to prevent positions from attending to subsequent positions. This masking, combined with fact that the output embeddings are offset by one position, ensures that the predictions for position i can depend only on the known outputs at positions less than i .
- *Attention*: An attention function can be described as mapping a query and a set of key-value pairs to an output, where the query, keys, values, and output are all vectors. The output is computed as a weighted sum of the values, where the weight assigned to each value is computed by a compatibility function of the query with the corresponding key.

1.6 Dataset

The dataset at our disposal describes a period of almost two years (from 02/02/2022 to 16/06/2023) and comes from a 978 kW photovoltaic plant located in the province of Bari. It consists of 3 inverters, 27 field panels, 1 meter, 1 solarimeter, 2 interface protections and 1 “system” device in which data from Solargis are stored. The dataset is organized into files, one for each type of device, representing each individual day, and the data is aggregated every 5 minutes. Each row contains a reference to the device it belongs to (`deviceName` and `deviceId`).

1.6.1 Inverter

Inside the files related to the inverters, we can find data such as the processor's operating temperature (`InternalTemperature`), various Alternating and Direct currents produced (`CurrentAC` and `CurrentDC`), Delivered Power, total energy produced by the individual inverter and other status and control bits that indicate various stages of the inverter's life (boot, reset, ready, etc.).

Down below a table with all the available features:

Name	Unit Symbol	Description

1.6.2 Junction Box

In the files related to the Junction Box or Combiner Box, we find data that describes the current production of the various strings they are connected to (`CurrentString1-7`, in general, each Junction Box manages 7 strings), some temperatures (such as `ModuleTemperature`), and some control bits to check proper operation.

Name	Unit Symbol	Description
CommunicationCode	-	Communication Code
Failure	-	Strings Alarm
CurrentString1	A	Current I1
CurrentString2	A	Current I2
CurrentString3	A	Current I3

1.6.3 Solargis

Solargis is a company specialized in providing solar data and forecasting services for photovoltaic installations and solar energy-related projects. Their main goal is to provide precise and reliable information on solar irradiation and solar weather conditions anywhere in the world. This data is essential for the design, optimization, and management of photovoltaic systems. Solargis collects and provides detailed data on global, direct, and diffuse solar irradiation at every geographical location. This data allows photovoltaic system developers to assess the amount of available solar energy in a given area, which is crucial for properly sizing the system and calculating production forecasts.

Table 1.5: Some Solargis data from 2022_08_01_Rofilo_NP00003174_plantDevice.csv file

Solar radiation takes a long journey until it reaches Earths surface. So when modelling solar radiation, various interactions of extra-terrestrial solar radiation with the Earths atmosphere, surface and objects are to be taken into account. The component that is neither reflected nor scattered, and which directly reaches the surface, is called direct radiation; this is the component that produces shadows. The component that is scattered by the atmosphere, and which reaches the ground is called diffuse radiation. The small part of the radiation reflected by the surface and reaching an inclined plane is called the reflected radiation. These three components together create global radiation.

In solar energy applications, the following parameters are commonly used in practice:

- Direct Normal Irradiation/Irradiance (DNI) is the component that is involved in thermal (concentrating solar power, CSP) and photovoltaic concentration technology (concentrated photovoltaic, CPV).
- Global Horizontal Irradiation/Irradiance (GHI) is the sum of direct and diffuse radiation received on a horizontal plane. GHI is a reference radiation for the comparison of climatic zones; it is also essential parameter for calculation of radiation on a tilted plane.
- Global Tilted Irradiation/Irradiance (GTI), or total radiation received on a surface with defined tilt and azimuth, fixed or sun-tracking. This is the sum of the scattered radiation, direct and reflected. It is a reference for photovoltaic (PV) applications, and can be occasionally affected by shadow.

Name	Unit Symbol	Description
SolargisGHI	W/m ²	Solargis Global Horizontal Irradiation
